

Figure 19. Graph of total amplification.

#### EXPERIMENTAL METHOD

The acoustic energy was measured by mounting a Piezo electric transducer on the head of the stud bolt. (See Figure 18). The energy per second was given as a function of the loading and recorded for an off-line analysis afterwards. The acoustic background spectrum showed the typical noise without any high energy events.

At 65 dB total amplification the RMS of the background was about 100mV with respect to 1500 mV peak value of the signal from the fracture of a pencil point at A (Figure 19). The test duration was about 15 minutes for one stud bolt as the load was increased slowly, with a number of hold periods in between to recognize possible crack extension. During the test no increase in the level of background noise occurred. Figure 3 shows the stud bolts that were considered for testing. Besides the studbolts that gave reflections at the ultrasonic testing also some bolts without crack indications were inspected with AET.

#### RESULTS

All stud bolts could be tested up to the maximum load level, although a significant difference in the acoustic emission energy was noted especially for the stud bolts that had given a defect indication at U.S. testing. Their behavior was clearly different from the faultless stud bolts (See Figure 25).

It was not possible to make a quantitative conclusion with respect to the defect size from this test, but if we see the curve of the acoustic energy as a function of the load and compare this with information from literature, then the conclusion seems justified that in stud bolt number 13 ( $H_2O_2$ , B) critical crack extension occurs at maximum test loading.

## Trials on Dispersion of Heavy Gas Clouds

The culmination of a long-term endeavor to rectify the scarcity of reliable data on heavy-gas dispersion.

J. McQuaid, Safety Engineering Laboratory, Sheffield, UK

Dispersion of heavy gas clouds at ground level in the atmosphere has been a subject of increasing interest over the past 10 to 15 years. The interest stems from the need to assess the hazard posed by large-scale storage and handling of flammable and toxic gases. These gases, if accidentally released to the atmosphere, often form low-lying clouds whose dispersion behavior is quite different to that of the usual atmospheric pollutants. Early experiments, although conducted at relatively small scale, clearly showed this difference in behavior (e.g., Burgess *et al* [3]). The clouds, due to their excess density over that of the surrounding atmosphere, were characteristically much wider and shallower than predicted by standard atmospheric dis-

persion models. The observations from the early experiments, coupled with the growth of risk assessment methodologies, stimulated the development of a number of predictive models. Many of these models were evaluated by Havens [6] on behalf of the US Coast Guard. He showed that the models exhibited very large differences in predictions when used to calculate the consequences of large accidental spillages of LNG.

Haven's evaluation had a seminal influence in that it highlighted the need to understand better the effects of the scale of release. Concurrently with the US developments, the UK Health and Safety Executive (HSE) embarked in 1975 on a long-term program of research on dispersion of
